ABSTRACT

The human brain's ability to adapt to environmental changes is obvious in specific sensory domains of experts, and olfaction is one of the least investigated senses. As we have previously demonstrated that olfactory expertise is related to functional brain modifications, we investigated here whether olfactory expertise is also coupled with structural changes. We used voxel-based morphometry to compare the gray-matter volume in student and professional perfumers, as well as untrained control subjects, and accounted for all methodological improvements that have been recently developed to limit possible errors associated with image processing. In all perfumers, we detected an increase in gray-matter volume in the bilateral gyrus rectus/medial orbital gyrus (GR/MOG), an orbitofrontal area that surrounds the olfactory sulcus. In addition, gray-matter volume in the anterior PC and left GR/MOG was positively correlated with experience in professional perfumers. We concluded that the acute olfactory knowledge acquired through extensive olfactory training leads to the structural reorganization of olfactory brain areas.

Keywords

Olfaction, Perfumer, Expertise, Gray-matter volume, Voxel-based morphometry, Structural reorganization

Introduction

Numerous studies in humans have indicated that functional and anatomical modifications occur in the brain because of learning and training. In experts with enhanced visual, auditory or motor skills, such as musicians and athletes, greater performance is associated with functional and structural brain changes in modality-specific brain areas, which supports the view that brain reorganization is associated with expertise.

What about olfactory expertise? Could the brain reorganization observed with expertise in other modalities be generalized to olfaction? This question has been addressed only once before, probably because human olfactory abilities are less essential for survival than other senses and are more poorly developed compared to those of other mammals, and because olfactory experts, such as perfumers, are rare. While exploring brain process related to odor mental imagery, we observed an expertise-dependent functional reorganization in olfactory and mnemonic brain areas, such as the primary olfactory (piriform) cortex (PC) and hippocampus, which was concomitant to enhanced behavioral performances with expertise. To the best of our knowledge, brain structural reorganization in olfactory expert has never been investigated. However, focusing on alterations of olfactory processes, several studies have shown gray matter (GM) atrophy in olfactory-related areas in patients suffering from anosmia, or hyposmia because of peripheral dysfunction or neurological disease. Whether subjects with olfactory expertise present modifications of GM volume in olfactory areas is an open question.

Computational morphometry tools allow for investigation of structural brain changes related to development, learning, expertise and pathology. The voxel-based morphometry (VBM) technique is broadly used and remains an active field of methodological research. Several pitfalls in image preprocessing, including inter-individual misregistration and errors in the segmentation procedure, skull-stripping and bias correction, and bias induced by improper templates and priors, are the subjects of vigorous debate in the neuroimaging community. However, methodological

improvements have recently been developed that may limit possible errors . First, the segmentation algorithm can include bias correction, and can now model not only brain tissues but also non-brain tissues. This allows removing potential contamination from soft tissues outside the brain, large vessels and skull. Second, a study-specific template can be created. Third, algorithms for diffeomorphic image registration with a high number of degrees of freedom can be employed to obtain accurate registration of each individual brain with a given template. In particular, the algorithm for “Diffeomorphic Anatomical Registration using Exponentiated Lie algebra” better known under the DARTEL acronym is considered as being among the best algorithms available . Fourth, the segmentation and the spatial registration procedure can be combined in a unified approach to improve preprocessing steps . A recent VBM test-retest study showed that when using all above-mentioned improvements as implemented in Statistical Parametric Mapping 8 (SPM8) using DARTEL, this permits to avoid obtaining most of the false positives . Fifth, voxels which feature low effect-size and very low variance can be artifactually significant . In order to reduce false positives, the newest SPM8 release (v.4010, April 04, 2011) includes a scheme to force such voxels to have low significance in VBM statistical analysis .

In the current study, we used structural magnetic resonance imaging (MRI) and the VBM pipeline with DARTEL in statistical parametric mapping (SPM8) software. We scanned 14 perfumers renowned for creating perfumes, 13 students from an international school of perfumery and 21 control subjects. We took advantage of variability in length of expertise in professional perfumers to identify structural brain reorganization that is associated with experience under the hypothesis that intensive olfactory training may lead to increased GM volumes in olfactory- and memory-related areas.

Materials and Methods

Subjects

Forty-eight healthy right-handed subjects participated in our study. The perfumers' group included 13 young experts (YE; 3 men; mean age, 23 years; range, 21–26 years) who were students at an international school of perfumery (Institut Supérieur International de la Parfumerie, de la Cosmétique et de l'Aromatique, Versailles, France), and 14 older experts (OE; 10 men; mean age, 42 years; range, 29–59 years) who were professionals known for creating perfumes. While the YE had been trained for 2 years at most as part of their education, all OE had 5–35 years of career-relevant business experience. The control group was composed of 21 untrained subjects, including 8 young controls (YC; 2 men; mean age, 25 years; range, 24–28 years) and 13 older controls (OC; 6 men; mean age, 40 years; range, 30–55 years). Subjects from both groups were matched in age ($F_{(1,47)} = 0.10, p = 0.712$) and gender ($\chi^2 = 0.34, p = 0.560$).

The exclusion criteria were rhinal disorders (e.g., a history of nasal-sinus surgery), pregnancy, ferrous implants (e.g., pacemakers and cochlear implants), claustrophobia, or any neurological disease. This study was conducted according to French regulations on biomedical experiments using healthy volunteers and according to the principles outlined in the Declaration of Helsinki. All subjects gave written informed consent, as required by the local Institutional Review Board.

Structural Data Acquisition

All structural images were acquired on a Philips NT 1.5-Tesla MRI scanner (Philips Medical Systems, Best, Netherlands) with a birdcage head coil. The high resolution anatomical images of the olfactory experts were acquired during an fMRI study investigating the neural substrates of olfactory imagery and on controls during a visual retinotopy protocol that was conducted on the same scanner with the same sequence and at the same period of time as the scanning of olfactory experts. A high-resolution (1 mm³) structural image was acquired with the same sequence for all

subjects using a 3-dimensional, T1-weighted gradient echo sequence [repetition time = 23.7 ms, echo time = 6.9 ms, flip angle = 28°, number of accumulations = 2]. This acquisition sequence type has been shown to be particularly efficient when studying the inner part of the cortex .

Structural Data Preprocessing

We processed and analyzed the structural data using a VBM approach and SPM8 software (www.fil.ion.ucl.ac.uk/spm/software/spm8/) with default parameters.

For the first step, each individual image was segmented using the 'New Segment' tool provided with the DARTEL toolbox . This procedure performs segmentation and spatial normalization in a unified generative model based on a mixture of Gaussians with spatial priors and bias correction. In addition, the algorithm includes non-brain tissues (dura, scalp and large vessels), which ensures that the calculation of GM images is uncontaminated by either the skull or large veins. This approach permits to skip the bias correction and skull-stripping procedure, which improves VBM preprocessing .

In a second step, a study-specific template was calculated from all subjects' GM and white matter (WM) images using the DARTEL framework . This diffeomorphic registration algorithm iteratively estimates the non-linear deformations that best align the GM and WM images together, which provides a common study-specific template and deformation field that parameterizes the deformations for each subject's image.

In a third step, to spatially normalize the images to the Montreal Neurological Institute (MNI) standard brain, we calculated the affine registration that realigned our study-specific template generated using DARTEL with the GM tissue probability map in the MNI space. For each subject, we applied a combination of the deformation field and affine registration to the GM and structural images of each individual. The spatially normalized GM segmented images were further modulated with the Jacobian of the deformation field to adjust for the resulting volume changes and derive GM volume-related images. The realigned structural images of all subjects were averaged for display purposes.

In a fourth step, to improve the sensitivity of the analysis to regional differences at a small spatial scale (required by small structures, such as the PC), we smoothed the GM volume images using a small isotropic Gaussian kernel with a 6-mm full width at half maximum. This kernel width ensures that any non-normality in the error term is sufficiently attenuated in balanced designs to render the tests valid .

Olfactory-related regions of interest

Statistical analyses were performed on brain areas known to play a role in olfactory and memory processing. As no probabilistic maps have been proposed for the olfactory areas, anatomical volume of interests (VOIs) in the PC, amygdala, hippocampus, insula and thalamus were drawn from the study-specific template realigned to the MNI using MRIcron (www.mccauslandcenter.sc.edu/mricro/mricron/) and human brain atlases . The VOIs were drawn from coronal slices for the PC (from $y = 12.5$ anterior to -2.7 posterior to the anterior commissure), amygdala (from $y = 0$ to -13.3), insula (from $y = -22$ to 36), and thalamus (from $y = 8$ to 29.2), and from sagittal slices for the hippocampus (from $x = -24$ to -38 on the left, and from $x = 24$ to 38 on the right). Based on previous data , the PC was divided along the y-axis into two areas, specifically, the anterior area (spreading from 12.5 to 4 mm) and posterior area (spreading from 4 to -2.7 mm). Orbitofrontal cortex (OFC) VOIs were spheres 10 mm in diameter located at coordinates previously identified by Gottfried and Zald in the left and right hemispheres (Talairach coordinates: $-22\ 30\ -17$ and $24\ 33\ -12$) as being the putative secondary olfactory cortex. These areas defining the human olfactory network were combined to form a binary mask to which we added orbital areas (Brodmann areas (BA) 11, 20 and 34) using the WFU_PickAtlas v2.4 software based on the Talairach Daemon database . This mask was further dilated by 6 mm (the same width as the smoothing kernel employed for GM volume images) for use as an explicit mask in subsequent VBM statistical analyses.

*Statistical Analysis**Voxel-based morphometry analysis*

As it was reported that the anatomical effects of expertise in musicians increase as a function of years of practice, we hypothesized that the effects of expertise could also be correlated with age in perfumers and not in naïve controls who have never undergone any olfactory training. Given this hypothesis, the effect of age was inhomogeneous among the four groups of subjects and had to be modeled separately for each sub-group. Voxelwise GM volume differences between experts and control subjects were statistically tested using multiple regression analysis, including four regressors of interest (age of older experts, older controls, young experts and young controls). To eliminate possible confounding factors associated with gender or with total GM volume, we applied two regressors of no-interest (gender and total GM volume, the latter being obtained using the '*get-totals.m*' matlab function, www.cs.ucl.ac.uk/staff/g.ridgway/vbm/). For statistical analysis of the GM images, we excluded all voxels with GM values below 0.2 (absolute threshold masking) to avoid possible edge effects between different tissue types and to only account for GM voxels with high GM volume content. The GM-volume statistical analysis was constrained within the explicit GM olfactory mask defined above.

We tested whether GM volumes differed globally between experts and controls $[(YE + OE) - (YC + OC)]$ and also assessed the effect of expertise in the younger and older experts compared to their respective controls (contrasts $[YE - YC]$ and $[OE - OC]$, respectively). To identify the areas commonly different between the two sub-groups of experts and their respective controls, we computed the voxels that reached the criterion of significance for both contrasts $[YE - YC]$ and $[OE - OC]$. Finally, to test for differences in brain volumes between the expert sub-groups, we performed contrasts for $[(YE - YC) - (OE - OC)]$ and $[(OE - OC) - (YE - YC)]$. For all the contrasts, we applied Student's *t*-test with a height of threshold on individual voxels such that $p_{uncorrected} < 0.001$ and a threshold on spatial extent such that the probability on the extent was $p_k < 0.05$.

VOI-based analysis

For each olfactory-related VOI and each of the 48 participants, we derived the adjusted values from the previous general linear model analysis, by removing any contribution from no-interest variables within the VOI. For each VOI, three-way ANOVA (Group x Age x Side) and mean *post-hoc* comparisons were performed using Statistica 6.0 (StatSoft®, Tulsa, OK, USA) to compare the degree of change in GM volume as a function of the groups (controls and experts), age (younger and older) and brain sides (left and right). We tested the null hypothesis that there were no significant changes of GM in each of the seven VOIs (the aPC, pPC, OFC, amygdala, hippocampus, insula and thalamus). To control for Type I error rate, we applied the Bonferroni correction by dividing the probability α per the number of VOIs ($p_{\text{corrected}} = 0.007$).

Regression analyses

On the bilateral aPC and pPC VOIs, and two GR/MOG clusters evidenced on the left side (-9 23 -15 and -8 26 -24) with classical general linear model analysis as being dependent of expertise, we performed linear regression analyses to test for significant relationships between the years of age and volume of GM either in older experts or in older controls using Statistica 6.0 (StatSoft®, Tulsa, OK, USA). In older experts, years from 20 years-old (when their training started) were considered as years of practice and thus reflected the length of expertise. In the controls matched in age, we also removed 20 years to their age in order to compare with the professional experts. The regression lines of the expert and control groups were compared for parallelism and common intercepts to respectively test whether the relationships between expertise and GM volume (slopes of the regression lines) were different, and whether the volume variations began at identical levels of expertise (intersection of the regression lines with the y-axis). As an effect of expertise on the grey-matter volume could be predicted for each of these 6 VOIs, we applied the Bonferroni correction ($p = 0.0083$).

Results

Statistical results of the analyses of GM volume in the four groups of subjects are presented in Table 1. When contrasting the GM volumes between all experts and controls [(YE + OE) – (YC + OC)], we observed a bilateral pattern of increased volume spreading from the gyrus rectus (GR) to the medial orbital gyrus (MOG), and an increased GM volume in the anterior cingulate gyrus and the caudate nucleus (Fig. 1A). In YE compared with YC (YE - YC), we observed an increased GM volume in the left and right GR/MOG and in the left anterior cingulate gyrus. In OE compared with OC (OE - OC), a higher GM volume was observed in an anterior area of the left GR/MOG and in the left caudate nucleus. Although reaching the criterion of significance at peak level only, the conjunction analysis between contrasts applied in both sub-groups of experts when compared to their respective controls [(YE - YC) and (OE - OC)] revealed a common pattern of increased GM volume in the right gyrus rectus (x y z coordinates, 9 27 -24). The interactions [(OE - OC) - (YE - YC)] and [(YE - YC) - (OE - OC)] did not reveal any significant differences in GM volume, demonstrating no significant influence of sub-groups on the effect of expertise. No significant decrease in GM volume was observed in experts when compared with controls regardless of the comparisons.

Anatomical VOI analyses did not reveal any significant group effect in the VOIs ($p_{\text{corrected}}$), although a group effect was noted in the posterior PC with a $p_{\text{uncorrected}}$ ($F(1,44) = 4.00, p = 0.044$), suggesting a volume of GM tending to be higher in experts than in control participants. Significant Group x Side interactions were observed for the amygdala ($F(1,44) = 13.01, p = 0.001$), insula ($F(1,44) = 56.99, p < 0.001$) and thalamus ($F(1,44) = 16.45, p < 0.001$); however, *post-hoc* comparisons did not show any significant difference between groups for a given side (p 's > 0.007), but only significant differences between both sides in experts and/or controls.

We subsequently examined whether the GM volume in older experts depended on the duration of practice (and therefore on the level of expertise). In the left gyrus rectus (Lower part: -9 23 -15;

Upper part: -8 26 -24; Fig. 2A), the volume of the GM was significantly positively correlated with the age (and therefore the level of expertise) in OE (Upper part: $r = 0.685$, $F(1,12) = 10.62$, $p = 0.007$; Lower part: $r = 0.677$, $F(1,12) = 10.13$, $p = 0.008$), while it tended to be significantly negatively correlated with age in EC in the upper part ($r = -0.649$, $F(1,11) = 8.00$, $p = 0.016$) and it was not significant in the lower part ($r = -0.50$, $F(1,11) = 3.58$, $p = 0.085$). Regression lines obtained in OE and OC were significantly not parallel in both areas (Upper part: $T(27) = 4.21$, $p < 0.001$; Lower part: $T(27) = 3.42$, $p = 0.002$), and they had common intercepts ($T(27) = 1.90$, $p = 0.068$ and $T(27) = 1.52$, $p = 0.139$, respectively).

The GM volume of the anterior PC (Fig. 3B) was not significantly positively correlated with expertise level in OE in the left ($r = 0.486$, $F(1,12) = 3.71$, $p = 0.078$) and the right ($r = 0.401$, $F(1,12) = 2.30$, $p = 0.155$) sides, but tended to be significantly negatively correlated ($p_{\text{uncorrected}}$) in OC in both sides (Left: $r = -0.582$, $F(1,11) = 5.64$, $p = 0.037$; Right: $r = -0.623$, $F(1,11) = 6.69$, $p = 0.023$). Regression lines for OE and OC data were significantly not parallel (Left: $T_{27} = 3.03$, $p = 0.005$; Right: $T(27) = 2.84$, $p = 0.009$) and had common intercepts for the right anterior PC ($T(27) = -1.74$, $p = 0.093$).

Discussion

By combining the structural imaging and VBM technique with the best and most recent improvements, we showed structural modifications related to olfactory expertise. Compared with naïve subjects, the student and professional perfumers mainly presented a bilateral GM increase in the GR/MOG, an area that marks the borders of the olfactory sulcus and that is adjacent to the putative secondary olfactory cortex. Furthermore, when considering the professional experts only, expertise seems to counteract the effect of age in the GR/MOG and anterior PC, as the GM volumes increased with years of practice, whereas they decreased with age in naïve subjects.

Structural and functional characteristics of the GR/MOG

All olfactory experts showed an increased GM volume in the GR/MOG compared with control subjects who had no expertise in olfaction. Volume increase was bilateral in the GR/MOG more posterior part and was left-sided in the more anterior part.

Very few studies have shown an increase of GM volume in olfactory areas in relation with olfactory abilities in normosmic volunteers. They demonstrated that the size of the olfactory bulb and/or the depth of the left olfactory sulcus significantly correlated with olfactory performances in healthy subjects and in individuals who became blind early in life. If the olfactory bulb is mostly considered to be a peripheral structure, the depth of the olfactory sulcus can reflect the size of the adjacent cerebral cortex. Using an automated method for extracting the cortical thickness, Frasnelli et al. found an increase in cortical thickness with higher olfactory abilities in an area surrounding the left olfactory sulcus in healthy volunteers. This region is very close to the GR/MOG evidenced in our study, and allows dismissing the interpretation of the current results as resulting from methodological artifact. Recently, applying classical volumetry and VBM methodologies in healthy subjects, Seubert et al. dissociated the functional contributions of olfactory peripheral and central areas. They found that the volume of the olfactory bulb increased with higher identification scores, while the volume of GM in the OFC was enhanced with better olfactory threshold and

discrimination performances. Because the authors limited their investigation to a unique area of the OFC that approximately covered the putative human olfactory OFC evidenced by Gottfried and Zald but did not include the GR/MOG regions, the comparison with our data is impossible. However, it is surprising that we did not observe any change of GM volume in this region in the odor experts.

What is the role of the GR/MOG region? In monkeys, the GR/MOG is referred as being area 11m and is a zone located at the level of the olfactory sulcus delimited by the dysgranular areas 13m, 13b and 14r . Studying architectonic maps and the intrinsic cortico-cortical connections within the orbital and the medial prefrontal cortex, Carmichael and Price distinguished two distinct networks, the “orbital network” (including in particular areas 13b and 13m) that receives inputs related to most of the sensory modalities and the “medial network” (including in particular areas 11m and 14r) that receives a few direct olfactory inputs, but does not receive inputs from other sensory modalities. Because all of the areas recognized in the macaque medial prefrontal cortex have their counterparts in humans , the question is to know what is the role of the GR/MOG in humans. In an attempt to explain the respective role of these two networks, the authors suggested that the orbital network appears to be related to feeding and reward, whereas the medial network seems to participate in the guidance of emotional behavior . Rather than a coarse medial/lateral distinction, Kahnt et al. recently identified 6 subdivisions in the human OFC from their functional connectivity profiles with other brain regions. They suggested a role of the medial and central-posterior regions in reward processing and reward learning, respectively.

In cerebral imaging studies on human olfactory processes, the GR/MOG was found to be activated in several studies , although often described with different labels (such as the rostromedial or posterior OFC, ventromedial prefrontal cortex, inferior frontal gyrus, cingulate gyrus, or subcallosum), depending on the atlases and nomenclatures. Interestingly, this brain region is different from the putative olfactory OFC evidenced by Gottfried and Zald . The GR/MOG could therefore be associated to more higher-order cognitive process in comparison to this putative

olfactory OFC which was identified from data for which no cognitive olfactory judgment and no aversive odorants were used. A functional segregation of valence neural representations has been observed in the OFC, the medial part being more strongly activated by pleasant odors, and the lateral part being more notably activated by unpleasant odors, a representation that holds even when the attributed hedonic properties are modulated by cognitive information. Similar findings were observed with taste and flavor, the processing of faces, and monetary reward and punishment. Since the perfumers intensively and daily use pleasant odorants in order to make fragrances, as suggested by testimonies, the question is whether this hyper-use can explain structural changes observed in the GR/MOG. Further investigations are needed to clarify this point.

We further observed additional GM changes in the anterior cingulate gyrus in student perfumers and in the caudate nucleus in professional perfumers, which are two areas that are commonly activated in olfaction. Structural modifications in these regions are in accordance with the cognitive functions that are widely used in experts of all types including perfumers. The anterior cingulate gyrus is predicted to play an important role in tasks requiring cognitive control in the presence of emotional stimuli while the caudate nucleus is highly involved in learning and memory.

Dynamic changes of GM volume in olfactory areas

Here, we observed that intensive olfactory training counteracts the effect of age in several brain regions. Thus, although the increases were not systematically significantly positively correlated with experience in these areas in older perfumers, they were strengthened by the fact that the GM volume was reduced with age in controls and that the respective slopes of both regression lines were then systematically significantly different. Thus, the older an individual gets, the more the anterior PC and GR/MOG volumes relatively increase in experts and the more they decrease in untrained subjects. Volume reduction in controls is consistent with the well-known decline of global GM volume with age. Hedman et al. have shown that after 35 years-old, a steady volume loss of 0.2 % per year is found, which accelerates gradually to an annual brain volume loss of 0.5 % at age 60.

Overall, these double morphometry data demonstrate a causal direction between olfactory

abilities and GM volume of olfactory areas. When the two lines of regression present a common intercept but different slopes, this means that experts and controls had the same GM volume at the same age (approximately 20 years old), but that this volume changes differently with respect to age by increasing in odor experts and decreasing in controls. These data also allow claiming that longer olfactory training leads to larger GM volumes, a finding that must be related to our previous results observed in the same subjects and showing behavioral performances enhanced with expertise . Structural changes in odor experts are further consistent with cross-sectional VBM studies that demonstrate learning-dependent changes in the adult human brain and suggest anatomical correlates for navigation, arithmetic, linguistic, procedural, and musical learning abilities . Structural changes have even been observed after brief periods of learning, such as after studying for three months after an exam or even after a very short spatial learning of 2 hours .

Neuronal mechanisms related to olfactory learning

Perceptual learning refers to a phenomenon whereby experience refines sensory perception through the differentiation of stimulus features, dimensions, or categories of items that was previously experienced. It has previously been showed that experience and familiarity enhance odor quality discrimination . Training to taste wine and beer also improves the ability to discriminate flavors . Recently, Li et al. showed that prolonged exposure (3.5 min) to a floral-smelling odorant enhances perceptual differentiation only for novel odorants that are related in odor quality or functional group, indicating that subjects become floral “experts.” This effect was paralleled by increased responses in the posterior PC and interestingly an area close to the medial OFC (-14 30 -14), as observed here. The authors speculated that this learning-induced plasticity could reflect two neuronal mechanisms, an enlargement in cortical receptive fields, which results in the recruitment of more neurons (spatial summation), or alternatively a synchronization of neuronal activity (temporal summation) .

The current experiment is the first to investigate the structural impact of odor long-term training. Perfumers live in an enriched olfactory environment and learn to characterize and recognize

numerous stimuli daily, and to discriminate often minute differences between them. This paper follows its functional counterpart in which we demonstrate a signal decrease in hyper-trained perfumers in olfactory (piriform cortex and OFC) and memory (hippocampus) brain regions when they generate a mental image of odor. A signal decrease could be because of a greater selectivity of neurons due to a decorrelation of their activity . Similar mechanisms have been shown in the antennal lobe of the honeybees trained on one odorant, the sensorial representation of that odorant becoming smaller, more compact, and nonoverlapping with other odorants and in rats trained to discriminate highly overlapping odorous mixtures . As an attempt to conciliate the structural and functional reorganizations of olfactory experts, we speculate that although cells become more selective after perceptual learning, perfumers could present an enlargement of the cortical surface dedicated to odor representation, and correlatively present a GM volume increase.

Cellular events underlying structural changes

The nature of the cellular events that underlie structural changes in the human brain is still unknown , although it is widely assumed that GM loss in neurodegeneration corresponds to neural loss . First, GM increase can be due to fast morphological changes such as the formation of new connections by dendritic spine growth . Thus, a three-day olfactory learning in rats is accompanied by a dendritic spine density increase (15%) along apical dendrites of PC pyramidal neurons, suggesting an increased number of excitatory synapses . Second, GM increase can be related to slow mechanisms, such as adult neurogenesis that has been reported in the olfactory bulb and the PC . In the olfactory bulb, it was associated with an improvement in short-term olfactory memory when mice were exposed daily to a novel enriched olfactory environment . Here, we suggest that a GM volume increase in the anterior PC could mainly result both from a fast remodeling of the intracortical neuronal network, but genesis of new neurons in this brain area cannot be excluded.

The current study showed that olfactory expertise is concomitant with a structural reorganization in primary areas and the OFC. We revealed a GM volume increase in the bilateral GR/MOG and a trend for a GM increase in the posterior PC in odor experts compared with naïve subjects. More strikingly, the GM volume in the left GR/MOG and bilateral anterior PC was positively correlated with experience. These findings are consistent with our previous data showing that perfumers present an expertise-dependent functional reorganization in olfactory and memory areas. In summary, together with our previous experiment, long-term olfactory training leads to the acquisition of highly specific knowledge, which enables the generation of odor mental images and is paralleled by the structural and functional reorganization of olfactory areas.

Legends

Fig. 1. Whole-brain structural modifications as a function of expertise. Increased GM volumes were observed in (A) the gyrus rectus in all experts (Exp) when compared with all controls (Cont), (B) the cingulate gyrus in young experts (YE) when compared with young controls (YC), and (C) the gyrus rectus and caudate nucleus in older experts (OE) when compared with older controls (OC).
